## HIGHLIGHTS

- Spherical  $\text{TiO}_2(\text{B})$  secondary particles are used as anode for lithium-ion batteries.
- The spherical  $\text{TiO}_2(\text{B})$  particles are advantageous for high electrode density.
- The spherical  $\text{TiO}_2(\text{B})$  electrodes have superior electronic connective property.
- Spherical  $\text{TiO}_2(\text{B})$  electrodes lead to high-rate capability and long-cycle life.
- The  $\text{TiO}_2(\text{B})/\text{NCM}$  cell exhibits high-power and a long-life of more than 3000 cycles.

## ABSTRACT

Electrochemical properties of micro-size spherical  $\text{TiO}_2(\text{B})$  secondary particles have been investigated in order to develop  $\text{TiO}_2(\text{B})$  anodes for lithium-ion batteries with high-power and long-life performance. The spherical  $\text{TiO}_2(\text{B})$  electrodes with a small amount of a carbon conductor additive had a high electrode density of  $2.2 \text{ g cm}^{-3}$  and a volumetric reversible capacity of  $475 \text{ mAh cm}^{-3}$  comparable to that of graphite electrodes. Compared with nano-size needle-like  $\text{TiO}_2(\text{B})$  electrodes, the spherical  $\text{TiO}_2(\text{B})$  electrodes exhibited higher-rate discharge capability and longer-cycle life performance. The impedance of the  $\text{TiO}_2(\text{B})/\text{electrolyte}$  interface model indicated that the charge transfer resistance  $R_c$  and the passivating film resistance  $R_f$  of the spherical  $\text{TiO}_2(\text{B})$  were much smaller than those of the needle-like one. The high-rate discharge and the long-cycle performance of the spherical  $\text{TiO}_2(\text{B})$  electrode are attributed to the superior electronic connective property and  $R_c$  and  $R_f$  values smaller than those of the needle-like one. Lithium-ion cells using the spherical  $\text{TiO}_2(\text{B})$  anodes and  $\text{LiNi}_{0.8}\text{Co}_{0.1}\text{Mn}_{0.1}\text{O}_2$  cathode with a capacity of 2.8 Ah exhibited a high energy density of  $100 \text{ Wh kg}^{-1}$ , a high output power density of  $1800 \text{ W kg}^{-1}$  for 10 s pulse, and a long cycle life of more than 3000 cycles.

## 1. Introduction

Development of large-scale lithium-ion batteries for automotive and stationary power storage applications has been progressing with a view to enhancing power, energy density, safety, life, quick-charge, and low-temperature performance. However, with regard to conventional lithium-ion batteries using graphite anodes for

these applications, there are important issues concerning limitations on life, safety, and low-temperature performance. For example, quick-charging and charging at low temperature lead to detrimental effects, namely, short cycle life and a safety issue because of the lithium plating on the surface of graphite anodes in lithium-ion batteries. Therefore, 1.5 V anode materials such as spinel  $\text{Li}_{4/3}\text{Ti}_5/3\text{O}_4$  (LTO) and titanium dioxides ( $\text{TiO}_2$ ), for example, anatase, rutile, monoclinic ( $\text{TiO}_2(\text{B})$ ), and brookite [1], have been extensively studied as anode materials in view of their life and safety superior to those of graphite and considering that their use would render lithium metal plating unnecessary. In particular, LTO is expected to be an attractive electrode material with zero-strain property, nano-sized particle, thermal stability, safety properties [2–11]. It has been demonstrated that lithium-ion batteries using LTO as the anode material offer high-power, quick-charging, long-life, and safety [9–14] and such batteries have been developed for automotive and stationary power storage applications [11,13,14].  $\text{TiO}_2$  is also an attractive anode material because its theoretical capacity ( $335 \text{ mAh g}^{-1}$ ) is larger than that of LTO ( $175 \text{ mAh g}^{-1}$ ). However lithium insertion and extraction for anatase, brookite, and rutile  $\text{TiO}_2$  is very slow, causing low rate capability and small reversible capacities in the case of use as a practical anode. Nano-size  $\text{TiO}_2$  powders have been studied in order to achieve high-rate performance.

Monoclinic  $\text{TiO}_2(\text{B})$  materials with various nanostructures such as nanowire and nanotube have been synthesized and are also expected to be as attractive anode materials because  $\text{TiO}_2(\text{B})$  exhibits higher reversible capacities and better cyclability than the other three forms of  $\text{TiO}_2$ . Lithium insertion into  $\text{TiO}_2(\text{B})$  particles by electrochemical reaction has been reported by several researchers [15–19]. A relatively low reversible capacity of less than  $200 \text{ mAh g}^{-1}$  has been reported for  $\text{TiO}_2(\text{B})$  synthesized by a solid-state reaction [15–17].  $\text{TiO}_2(\text{B})$  nanowire [20,21] and nanotube [22,23] prepared by hydrothermal reaction exhibited a high reversible capacity of  $240\text{--}280 \text{ mAh g}^{-1}$ . Compared with bulk forms, nanostructured forms of  $\text{TiO}_2(\text{B})$  enhance the reversible capacity and the rate capability.  $\text{TiO}_2(\text{B})$  nanoparticles prepared by hydrothermal reaction also indicated a high reversible capacity of  $247 \text{ mAh g}^{-1}$  and a significantly high rate capability [24]. However, a tap density of nanoparticulate  $\text{TiO}_2(\text{B})$  is lower than that of the bulk, which results in a low volumetric energy density of the battery. The coulombic efficiency at the first cycle decreases with the particle size, which also results in the low energy density. It is necessary to use  $\text{TiO}_2(\text{B})$  electrodes with a large amount of carbon conductor additive, such as ketjen black (KB) or acetylene black (AB), in order to enhance the electrode performance, but the additive causes low electrode density. Satio et al. reported that an optimized  $\text{TiO}_2(\text{B})$  composite electrode with 10 wt% KB additive showed the highest gravimetric discharge capacity of  $314.4 \text{ mAh g}^{-1}$  but a low volumetric discharge capacity of  $233 \text{ mAh cm}^{-3}$  because of the low electrode density of  $0.74 \text{ g cm}^{-3}$  [25].

We have also studied synthesis conditions, electrochemical properties, and lithium storage of  $\text{TiO}_2(\text{B})$  prepared by the solid-state reaction in order to understand the effects of the reversible capacity, cycle performance, and the rate capability of anode [26,27]. To further develop  $\text{TiO}_2(\text{B})$  anode for practical lithium-ion batteries with high-density electrode, high-power, and long-life performance, it is necessary to improve the rate capability, coulombic efficiency, and cycle life performance of  $\text{TiO}_2(\text{B})$  electrodes by using high-density  $\text{TiO}_2(\text{B})$  electrodes. In our investigation of the promising  $\text{TiO}_2(\text{B})$  particles for the anode application, we compared the electrochemical properties of micro-size spherical  $\text{TiO}_2(\text{B})$  and nano-size  $\text{TiO}_2(\text{B})$  particles. The micro-size spherical  $\text{TiO}_2(\text{B})$  particles are expected to realize high-density electrodes

because spherical particles have a high tap density. This paper reports on the electrochemical properties and performance of micro-size spherical  $\text{TiO}_2(\text{B})$  secondary particles applied as anode materials in lithium-ion batteries for automotive and stationary power applications.

## 2. Experimental

The micro-size spherical  $\text{TiO}_2(\text{B})$  particles were prepared by following method. The precursor  $\text{K}_2\text{Ti}_4\text{O}_9$  was prepared by a conventional solid-state reaction method. The mixture of raw materials such as  $\text{K}_2\text{CO}_3$  and  $\text{TiO}_2$  was dispersed in distilled water with a concentration of  $470 \text{ g L}^{-1}$ . The mixed slurry was spray dried to form secondary particles with an average size of  $15 \mu\text{m}$  at Titan Kogyo, Ltd., which was heated at  $1000^\circ\text{C}$  for 1 h. The granulated  $\text{K}_2\text{Ti}_4\text{O}_9$  particles were proton exchanged with  $1.8 \text{ mol l}^{-1} \text{ H}_2\text{SO}_4$  to obtain  $\text{H}_2\text{Ti}_4\text{O}_9$  as an intermediate compound. Finally, micro-size spherical  $\text{TiO}_2(\text{B})$  secondary particles were obtained by dehydrating the intermediate powder as reported in our previous paper [26]. To make comparison of primary and secondary particles of  $\text{TiO}_2(\text{B})$  on electrochemical properties, the spherical  $\text{TiO}_2(\text{B})$  secondary particles were disintegrated by grinding to obtain the needle-like  $\text{TiO}_2(\text{B})$  primary particles.

Fig. 1 shows SEM images of the spherical  $\text{TiO}_2(\text{B})$  secondary and the needle-like primary particles. The spherical secondary particle consists of nano-size needle-like  $\text{TiO}_2(\text{B})$  primary particles. Average particle sizes (diameter) of the spherical  $\text{TiO}_2(\text{B})$

Fig. 1. SEM images of spherical  $\text{TiO}_2(\text{B})$  secondary particles (a) and needle-like  $\text{TiO}_2(\text{B})$  primary particles (b).

secondary particles and the needle-like primary particles were about 10 and 0.5  $\mu\text{m}$ , respectively. Brunauer-Emmett-Teller (BET) specific surface areas of the spherical  $\text{TiO}_2(\text{B})$  secondary particles and the needle-like primary particles were 17.7 and 19.2  $\text{m}^2 \text{g}^{-1}$ , respectively.

The  $\text{TiO}_2(\text{B})$  composite electrodes were prepared from a paste mixture of 92 wt%  $\text{TiO}_2(\text{B})$  powder, 2 wt% carboxymethylcellulose (CMC) binder, 2 wt% styrene-butadiene (SBR) binder, and 4 wt% AB conductor in an aqueous solution. The paste was coated on aluminum foil and then dried. The  $\text{TiO}_2(\text{B})$  electrodes were pressed to obtain the electrode density of 2.2  $\text{g cm}^{-3}$ .  $\text{Li}_{4/3}\text{Ti}_5/3\text{O}_4$  (LTO) composite electrode was also prepared in the same manner as described previously [12] in order to compare the performance of  $\text{TiO}_2(\text{B})$  electrodes. The average particle size of LTO was about 0.9  $\mu\text{m}$ . The electrodes were dried under vacuum at 85  $^\circ\text{C}$  for 24 h before electrochemical measurements. Electrochemical measurements were performed by using the spherical  $\text{TiO}_2(\text{B})$ , the needle-like  $\text{TiO}_2(\text{B})$ , and the LTO electrodes with electrode material loading of 2 and 10  $\text{mg cm}^{-2}$  on the aluminum foil corresponding to the electrode thicknesses of 9 and 45  $\mu\text{m}$ .

Charge (lithium insertion)-discharge (lithium extraction) cycling tests, rate performance, and impedance measurements of the  $\text{TiO}_2(\text{B})$  and the LTO electrodes were carried out using a three-electrode glass cell constructed using the  $\text{TiO}_2(\text{B})$  or the LTO electrodes ( $2 \times 2 \text{ cm}$ ), a Li metal chip reference electrode, a Li metal counter electrode, a glass filter separator, and a 1 M  $\text{LiPF}_6$  in a mixed ethylene carbonate (EC) and diethyle carbonate (DEC) (1:2 by volume) electrolyte. Galvanostatic charge-discharge cycling tests of the  $\text{TiO}_2(\text{B})$  electrodes were carried out between 1.3 and 3 V at 100  $\text{mA g}^{-1}$ . 1 C rate for  $\text{TiO}_2(\text{B})$  and LTO electrode are 200 and 170  $\text{mA g}^{-1}$ , respectively. Impedance measurements of the  $\text{TiO}_2(\text{B})$  electrodes were carried out under the open-circuit potentials between 1.1 and 1.59 V vs.  $\text{Li/Li}^+$  after charging in the frequency range of  $3 \times 10^5$  to  $5 \times 10^{-2} \text{ Hz}$ . All experiments were carried out at 24–25  $^\circ\text{C}$  in a dry atmosphere. We determined the charge-transfer resistance  $R_c$  and the passivating film resistance  $R_f$  using an equivalent circuit consists of two parallel circuits in series. We used a frequency range of 19 Hz–60 kHz for  $R_c$  and 0.3 Hz–190 Hz for  $R_f$ , respectively.

Prototype  $\text{TiO}_2(\text{B})/\text{LiNi}_{0.8}\text{Co}_{0.1}\text{Mn}_{0.1}\text{O}_2$  (NCM) pouch cells with a capacity of 2.8 A h were used in order to evaluate cycle life, discharge rate performance, and power capability for automotive and stationary power applications. The  $\text{TiO}_2(\text{B})/\text{NCM}$  cells were constructed by using the spherical  $\text{TiO}_2(\text{B})$  anode with the electrode material loading of 10  $\text{mg cm}^{-2}$ , the NCM cathode with the electrode material loading of 9.2  $\text{mg cm}^{-2}$ , an electrolyte, a polyethylene separator, and a laminated film pouch cell. The NCM cathode was prepared from a paste mixture of 92.6 wt% NCM powder from a commercial sample, 2.8 wt% poly(vinylidene fluoride) binder, and 4 wt% carbon conductor in N-methyl pyrrolidone. The paste was coated on aluminum foil and then dried. The NCM cathode was pressed to obtain the electrode density of 3.2  $\text{g cm}^{-3}$ . The anode-cathode capacity balance in cells was set to be almost equal. The electrolyte was a 1 M solution of  $\text{LiPF}_6$  in a mixed propylene carbonate (PC) and DEC (1:2 by volume) solvent.

The discharge performance of  $\text{TiO}_2(\text{B})/\text{NCM}$  cell was measured at 25  $^\circ\text{C}$  by various discharge currents from 0.56 to 22.4 A down to 1.5 V after CC-V (constant current-constant voltage) charging at 2.8 A constant current up to 2.9 V of constant voltage to 0.14 A of cut-off current. We selected 1 C rate of 2.8 A. Charge-discharge cycling tests were carried out between 2.9 V and 1.5 V at 1 C rate at 25  $^\circ\text{C}$ . The power densities for output and input for 10 s were calculated from Hybrid Pulse Power Characterization (HPPC) test [28].

Fig. 2. Charge-discharge potential curves of the spherical  $\text{TiO}_2(\text{B})$  electrodes with different minimum charge potentials between 1.0 and 1.4 V at the first cycle.

### 3. Results and discussion

#### 3.1. Electrochemical properties of $\text{TiO}_2(\text{B})$ electrodes

Electrochemical properties of lithium insertion and extraction for  $\text{TiO}_2(\text{B})$  have been characterized by galvanostatic charge (lithium insertion) - discharge (lithium extraction) tests. Fig. 2 shows the charge-discharge potential curves of the spherical  $\text{TiO}_2(\text{B})$  electrodes at various charge cut-off potentials at the first cycle. The discharge capacity (reversible capacity) increased with decreasing the charge cut-off potential from 1.4 to 1.0 V vs.  $\text{Li/Li}^+$ . Gravimetric reversible capacity and volumetric reversible capacity after 1.0 V charging were 240  $\text{mAh g}^{-1}$  and 528  $\text{mAh cm}^{-3}$ , respectively. However, lithium insertion into  $\text{TiO}_2(\text{B})$  at the lower potential below 1.3 V vs.  $\text{Li/Li}^+$  had a large polarization [27], which means that in the practice the  $\text{TiO}_2(\text{B})$  anode takes a long time to become fully charged below 1.3 V. The low potential limit for  $\text{TiO}_2(\text{B})$  should be set at 1.2 V vs.  $\text{Li/Li}^+$  or higher because of the improvement for cyclability [29]. Therefore, charge-discharge cycling tests of  $\text{TiO}_2(\text{B})$  electrodes were performed between 1.3 and 3 V. Fig. 3 shows a comparison of charge-discharge

Fig. 3. Comparison of charge-discharge potential curves of the spherical  $\text{TiO}_2(\text{B})$  (a), the needle-like  $\text{TiO}_2(\text{B})$  (b), and LTO (c) electrode between 1.3 and 3.0 V vs.  $\text{Li/Li}^+$  at the first cycle.

properties of the spherical  $\text{TiO}_2(\text{B})$ , the needle-like  $\text{TiO}_2(\text{B})$ , and the LTO electrode at the first cycle. The spherical and the needle-like  $\text{TiO}_2(\text{B})$  electrode had high gravimetric reversible capacities of  $216 \text{ mA g}^{-1}$  and  $212 \text{ mA g}^{-1}$ , respectively compared to that of LTO electrode ( $169 \text{ mA h g}^{-1}$ ). The volumetric reversible capacity of the spherical  $\text{TiO}_2(\text{B})$  electrodes was  $475 \text{ mA h cm}^{-3}$ , which is comparable to that of graphite electrodes with the electrode density of ca.  $1.4 \text{ g cm}^{-3}$  [30,31]. The coulombic efficiency of the spherical  $\text{TiO}_2(\text{B})$ , the needle-like  $\text{TiO}_2(\text{B})$ , and the LTO electrodes at the first cycle was 90.4, 88.7, and 98%, respectively. These values of  $\text{TiO}_2(\text{B})$  electrodes were lower than that of the LTO electrode. Therefore, it is necessary to select a high-capacity cathode material with the coulombic efficiency of around 90% if the higher capacity of  $\text{TiO}_2(\text{B})$  than that of LTO is available for practical battery use.  $\text{LiNi}_x\text{Co}_y\text{Mn}_{1-x-y}\text{O}_2$  (NCM) as the cathode in combination with  $\text{TiO}_2(\text{B})$  anode is more promising than  $\text{LiCoO}_2$  and  $\text{LiMn}_2\text{O}_4$  because of the higher capacity and the lower coulombic efficiency for  $\text{LiNi}_x\text{Co}_y\text{Mn}_{1-x-y}\text{O}_2$  (NCM). The needle-like  $\text{TiO}_2(\text{B})$  electrode had a larger polarization and a slightly lower coulombic efficiency than those of the spherical  $\text{TiO}_2(\text{B})$  electrode. We consider that a small amount of carbon conductor additive in the needle-like  $\text{TiO}_2(\text{B})$  electrode is insufficient to work as the electronic conductor. Therefore, influence of  $\text{TiO}_2(\text{B})$  electrode thickness on

the electrode performance has been investigated by the discharge-rare performance tests of the  $\text{TiO}_2(\text{B})$  electrodes with two different thicknesses.

Fig. 4 shows discharge potential curves of the spherical and the needle-like  $\text{TiO}_2(\text{B})$  thin electrode with the loading of  $2 \text{ mg cm}^{-2}$  at various discharge rates of 0.2–20 C. The spherical  $\text{TiO}_2(\text{B})$  thin electrode had the higher capacities with a smaller polarization at more than 10 C rate ( $2000 \text{ mA g}^{-1}$ ) than those of the needle-like one. The discharge capacities of spherical and needle-like  $\text{TiO}_2(\text{B})$  thin electrodes at a high rate of 20 C ( $4000 \text{ mA g}^{-1}$ ) were 176 and  $113 \text{ mA h g}^{-1}$ , respectively. The capacity retention of spherical and needle-like  $\text{TiO}_2(\text{B})$  thin electrode at 20 C rate were 83 and 54%, respectively. Fig. 5 shows the discharge potential curves of the spherical and the needle-like  $\text{TiO}_2(\text{B})$  thick electrodes with the loading of  $10 \text{ mg cm}^{-2}$  at various discharge rates of 0.2–10 C. It was clearly observed that the needle-like  $\text{TiO}_2(\text{B})$  thick electrode had a large capacity fading with a large polarization at more than 1 C rate whereas the spherical  $\text{TiO}_2(\text{B})$  thick electrode did not. Fig. 6 shows discharge rate capability of thin and thick electrodes with the spherical, the needle-like  $\text{TiO}_2(\text{B})$ , and the LTO. The rate capability of the spherical  $\text{TiO}_2(\text{B})$  thin electrode was superior to that of the needle-like one and comparable to that of LTO thin

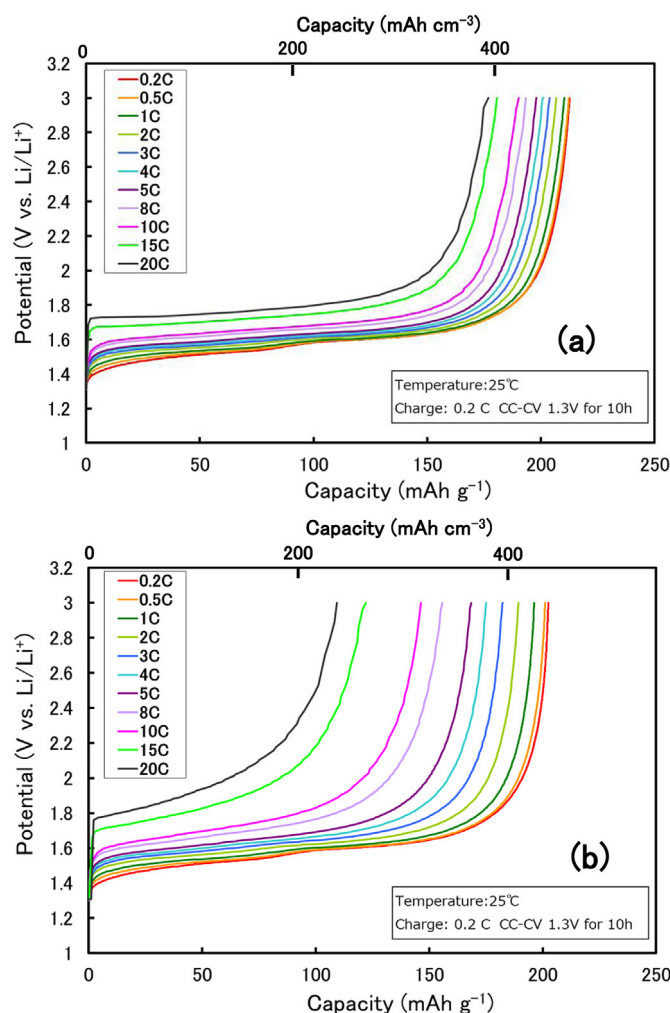

Fig. 4. Discharge potential curves of the spherical  $\text{TiO}_2(\text{B})$  (a) and the needle-like  $\text{TiO}_2(\text{B})$  (b) thin electrode with  $9 \mu\text{m}$  thickness at various discharge rates. 1 C rate:  $200 \text{ mA g}^{-1}$ .

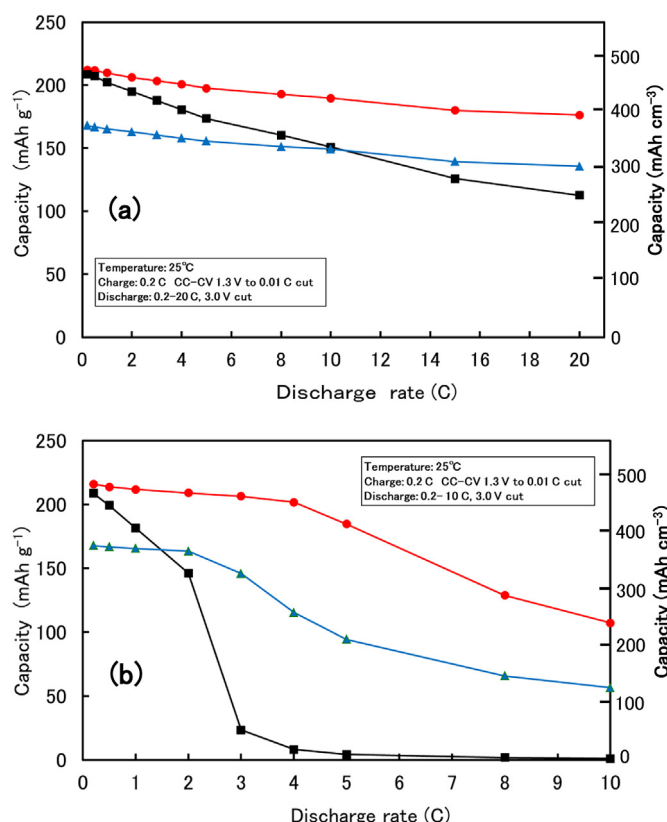

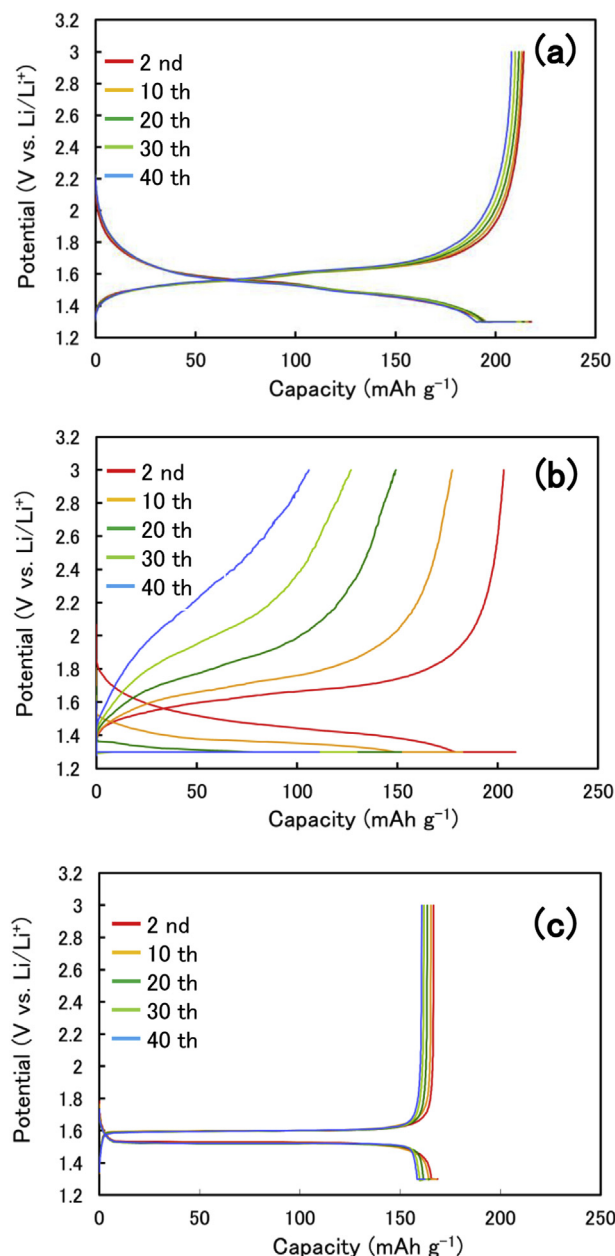

Fig. 5. Discharge potential curves of the spherical  $\text{TiO}_2(\text{B})$  (a) and the needle-like  $\text{TiO}_2(\text{B})$  (b) thick electrode with  $45 \mu\text{m}$  thickness at various discharge rates. 1 C rate:  $200 \text{ mA g}^{-1}$ .

**Fig. 6.** Discharge capacities of the thin electrodes (a) and the thick electrodes (b) of the spherical  $\text{TiO}_2(\text{B})$  (●), the needle-like  $\text{TiO}_2(\text{B})$  (■), and the LTO (▲) at various discharge rates. 1 C rate for  $\text{TiO}_2(\text{B})$  and LTO electrode are  $200 \text{ mA g}^{-1}$  and  $170 \text{ mA g}^{-1}$ , respectively.

electrode. In the case of thick electrodes, it was noted that the discharge rate capability of the spherical  $\text{TiO}_2(\text{B})$  thick electrode was considerably superior to that of the needle-like  $\text{TiO}_2(\text{B})$  and the LTO electrodes. We consider that the electronic connection between the micro-size spherical  $\text{TiO}_2(\text{B})$  secondary particles and a small amount of the carbon conductor additive is much better than that of the needle-like  $\text{TiO}_2(\text{B})$  and the fine LTO particles, which maintains good homogeneous electrochemical reaction in the thick electrode even at high rate discharge. Therefore, the spherical  $\text{TiO}_2(\text{B})$  secondary particles are suitable for used as the thick anodes in lithium-ion batteries to enhance the energy density. Figs. 7 and 8 show cycle performance of the spherical  $\text{TiO}_2(\text{B})$ , the needle-like  $\text{TiO}_2(\text{B})$ , and the LTO thick electrode. The spherical  $\text{TiO}_2(\text{B})$  and the LTO electrodes exhibited a small change in the voltage curves during the cycles. The needle-like  $\text{TiO}_2(\text{B})$  had a large polarization and a large capacity fading during the cycles. The cyclability of the spherical  $\text{TiO}_2(\text{B})$  thick electrode was considerably superior to that of the needle-like one and comparable to that of the LTO thick electrode. The spherical  $\text{TiO}_2(\text{B})$  and the LTO electrodes had a very small increase in polarization as the cycle number proceeded. On the contrary, the capacity of the needle-like  $\text{TiO}_2(\text{B})$  electrode decreased considerably with increasing the polarization. These results indicate that maintaining high electronic conductivity in  $\text{TiO}_2(\text{B})$  electrodes during the charge–discharge cycling is very important for good cyclability. The spherical  $\text{TiO}_2(\text{B})$  secondary particles have an advantage of a very good electronic connection between  $\text{TiO}_2(\text{B})$  particles and the carbon conductor during cycling, which leads to good cyclability of the  $\text{TiO}_2(\text{B})$  with the high electrode density.

**Fig. 7.** Variations in the charge–discharge potential curves of the spherical  $\text{TiO}_2(\text{B})$  (a), the needle-like  $\text{TiO}_2(\text{B})$  (b), and LTO (c) thick electrode during the cycles at 0.5 C rate.

### 3.2. Impedance spectroscopy of $\text{TiO}_2(\text{B})$ electrodes

Fig. 9 shows typical AC-impedance spectra of spherical and needle-like  $\text{Li}_x\text{TiO}_2(\text{B})$  electrodes at  $x = 0.63$  after the first charge–discharge cycle. The impedance spectrum exhibits a depressed semicircle or a few semicircles in the higher frequency range and a straight line in the lower frequency range. We consider that the semicircle can be interpreted as resulting from the charge-transfer process and the passivating film formed on the  $\text{TiO}_2(\text{B})$ .  $\text{TiO}_2(\text{B})$  particles with a large surface area are the electrochemically active and react with the electrolyte below 1.5 V vs.  $\text{Li/Li}^+$ , which leads to formation of the passivating product on a fresh  $\text{TiO}_2(\text{B})$  surface. The semicircle of the needle-like  $\text{TiO}_2(\text{B})$  electrode was larger than that of the spherical  $\text{TiO}_2(\text{B})$  electrode. The impedance of the  $\text{TiO}_2(\text{B})$ /electrolyte interface was modeled by a simple equivalent circuit as shown in Fig. 9. The equivalent circuit consists of two parallel

Fig. 8. Discharge capacities vs cycle number of the spherical  $\text{TiO}_2(\text{B})$  (●), the needle-like  $\text{TiO}_2(\text{B})$  (■), and the LTO (▲) thick electrode.

circuits in series.  $R_o$  is the ohmic resistance, and  $R_c$  and  $R_f$  are the charge-transfer resistance and the passivating film resistance, respectively.  $W$  is the Warburg impedance, and  $C_d$  and  $C_f$  are capacities corresponding to  $R_c$  and  $R_f$ , respectively. Variation of the impedance spectra of  $\text{TiO}_2(\text{B})$  electrodes with lithium insertion was characterized by using the equivalent circuit. Fig. 10 shows variation of  $R_c$  and  $R_f$  with  $x$  in  $\text{Li}_x\text{TiO}_2(\text{B})$ .  $R_c$  varied significantly with  $x$ . Such a variation of  $R_c$  for  $\text{TiO}_2(\text{B})$  electrodes is caused by the charge-transfer resistance for lithium insertion into  $\text{TiO}_2(\text{B})$  with a single-phase reaction. It is noted that  $R_c$  for the spherical  $\text{TiO}_2(\text{B})$  is much smaller than that of the needle-like one. Specifically, the difference of  $R_c$  between spherical and needle-like  $\text{TiO}_2(\text{B})$  increased with a decrease in  $x$  of  $<0.6$ . The electronic conductivity of  $\text{TiO}_2(\text{B})$  is gradually changed from a conductor to an insulator with decreasing  $x$  value. This phenomena would result in a small available surface area for the charge transfer reaction in the range of  $x < 0.6$ , especially in the needle-like  $\text{TiO}_2(\text{B})$  electrode due to its poor electronic condition path. We consider that the electronic connection between the spherical  $\text{TiO}_2(\text{B})$  particles and the carbon conductor is much better than that of the needle-like one.

Fig. 9. AC-impedance spectra of the spherical  $\text{TiO}_2(\text{B})$  (●) and the needle-like  $\text{TiO}_2(\text{B})$  (■) thick electrode at 1.4 V.

Fig. 10. Variations of  $R_c$  and  $R_f$  for the spherical  $\text{TiO}_2(\text{B})$  and the needle-like  $\text{TiO}_2(\text{B})$  electrode with  $x$  in  $\text{Li}_x\text{TiO}_2(\text{B})$ .

Therefore, by using  $\text{TiO}_2(\text{B})$  electrodes containing even a small amount of carbon conductor additive, the spherical  $\text{TiO}_2(\text{B})$  particles with the good electronic connective property are considered to have a large available surface area for the charge transfer reaction of lithium insertion and extraction.  $R_f$  was independent of  $x$  because  $R_f$  is associated with the film.  $R_f$  for the needle-like  $\text{TiO}_2(\text{B})$  electrode was larger than that for the spherical  $\text{TiO}_2(\text{B})$  electrode. We consider that such a larger  $R_f$  for the needle-like  $\text{TiO}_2(\text{B})$  electrode is due to the thicker film formation. The high-rate discharge and the long-cycle life performance of the spherical  $\text{TiO}_2(\text{B})$  electrode are attributed to the  $R_c$  and  $R_f$  values smaller than those of the needle-like one.

### 3.3. Performance of prototype $\text{TiO}_2(\text{B})/\text{NCM}$ cells

Prototype  $\text{TiO}_2(\text{B})/\text{NCM}$  pouch cells with a combination of the spherical  $\text{TiO}_2(\text{B})$  thick anode and a  $\text{LiNi}_{0.8}\text{Co}_{0.1}\text{Mn}_{0.1}\text{O}_2$  cathode have been developed for enhancing the energy density because the  $\text{LiNi}_{0.8}\text{Co}_{0.1}\text{Mn}_{0.1}\text{O}_2$  cathode had a high capacity of  $175 \text{ mAh g}^{-1}$  and a coulombic efficiency of 89% that was almost the same as that of the  $\text{TiO}_2(\text{B})$  anode at the first cycle. The specifications of the  $\text{TiO}_2(\text{B})/\text{NCM}$  cell are summarized in Table 1. The nominal capacity, the nominal voltage, and the energy density were 2.8 Ah, 2.3 V, and  $100 \text{ Wh kg}^{-1}$ , respectively. Discharge curves of the  $\text{TiO}_2(\text{B})/\text{NCM}$  cell at various discharge rates are shown in Fig. 11. The discharge capacity curves at 4 C (11.2 A) and 8 C (22.4 A) rate showed the capacity retention of 88.5 and 55.5%, respectively. The discharge rate capability decreased considerably at more than 4 C rate. Such a rate capability is acceptable for stationary power applications but insufficient for plug-in hybrid electric vehicle (PHEV) and electric vehicle (EV) applications. Fig. 12 shows pulse-power capability for

Table 1  
Specifications of prototype  $\text{TiO}_2(\text{B})/\text{LiNi}_{0.8}\text{Co}_{0.1}\text{Mn}_{0.1}\text{O}_2$  cell.

| Cell  | $\text{TiO}_2(\text{B})/\text{NCM}$ cell |
|---|--|
| Case  | Al laminated film                        |
| Dimension (mm)  | $110 \times 72 \times 4.3$               |
| Weight (g)  | 64                                       |
| Nominal capacity (Ah)   | 2.8                                      |
| Nominal voltage (V)   | 2.3                                      |
| 10 s output power density ( $\text{W kg}^{-1}$ ) <sup>a</sup> | 1800                                     |
| 10 s input power density ( $\text{W kg}^{-1}$ ) <sup>a</sup>  | 2600                                     |
| Energy density ( $\text{Wh kg}^{-1}$ )                        | 100                                      |

<sup>a</sup> At 50%SOC and 25 °C.

Fig. 11. Discharge curves of the  $\text{TiO}_2(\text{B})/\text{LiNi}_{0.8}\text{Co}_{0.1}\text{Mn}_{0.1}\text{O}_2$  cell at various discharge rates. 1 C rate: 2.8 A.

Fig. 12. Input and output power capability of the  $\text{TiO}_2(\text{B})/\text{LiNi}_{0.8}\text{Co}_{0.1}\text{Mn}_{0.1}\text{O}_2$  cell at 25 °C for 10 s pulse by HPPC testing.

the  $\text{TiO}_2(\text{B})/\text{NCM}$  cell obtained by HPPC testing at 25 °C. The maximum output and input power density for 10 s at 50% SOC were 1900  $\text{W kg}^{-1}$  and 2500  $\text{W kg}^{-1}$ . The input power density of more than 2500  $\text{W kg}^{-1}$  was maintained in the low SOC range of 20–50 %, which is suitable for regenerating in plug-in hybrid electric vehicles (PHEV). The output power density of more than 1500  $\text{W kg}^{-1}$

Fig. 13. Cycle performance of the  $\text{TiO}_2(\text{B})/\text{LiNi}_{0.8}\text{Co}_{0.1}\text{Mn}_{0.1}\text{O}_2$  cell at 25 °C and 1 C rate.

was maintained at more than 30% SOC. The discharge rate and the output power were inferior to those of LTO/NCM cell [14]. Further improvement of both the discharge rate performance and the output pulse-power capability is necessary for PHEV and EV applications.

Fig. 13 shows cycle life performance of the  $\text{TiO}_2(\text{B})/\text{NCM}$  cell by the charge–discharge cycling at 1 C rate between 1.5 and 2.9 V in 100% SOC width. The capacity retention after 3000 cycles was 80%, which is acceptable for EV and stationary power applications. However, the cycle life performance of the  $\text{TiO}_2(\text{B})/\text{NCM}$  cell should be further improved to be comparable to that of the LTO/NCM cell [14]. We consider that the capacity decline during the cycling is mainly caused by an increase in resistance for  $\text{TiO}_2(\text{B})$  anodes because  $\text{TiO}_2(\text{B})$  has a large surface area and a larger volume change during the cycling compared to that of LTO. Therefore, we are now developing  $\text{TiO}_2(\text{B})$  with the long cycle performance comparable to LTO.

#### 4. Conclusions

In our investigation of the electrochemical properties and the performance of micro-size spherical  $\text{TiO}_2(\text{B})$  secondary particle anodes for high-power and long-life lithium-ion batteries, we compared those of needle-like  $\text{TiO}_2(\text{B})$  and LTO particles. The spherical  $\text{TiO}_2(\text{B})$  electrodes with the high electrode density of 2.2  $\text{g cm}^{-3}$  to which a small amount (4 wt%) of AB conductor was added had a high coulombic efficiency of 90% at the first cycle and a reversible volumetric reversible capacity of 475  $\text{mAh cm}^{-3}$  (216  $\text{mAh g}^{-1}$ ) after 1.3 V vs.  $\text{Li/Li}^+$  charging, which values are comparable to those of graphite. Comparison of discharge rate capability and cycle life performance of the spherical  $\text{TiO}_2(\text{B})$ , the needle-like  $\text{TiO}_2(\text{B})$ , and the LTO electrodes revealed that the discharge rate and the cycle life performance of the spherical  $\text{TiO}_2(\text{B})$  electrodes were considerably superior to those of the needle-like  $\text{TiO}_2(\text{B})$  electrodes. The decline in the discharge rate capability of the spherical  $\text{TiO}_2(\text{B})$  thick electrode was smaller than that of the needle-like  $\text{TiO}_2(\text{B})$  thick electrode. Impedance spectrum of the spherical  $\text{TiO}_2(\text{B})$  electrode was observed to be significantly smaller than that of the needle-like one. The impedance of  $\text{TiO}_2(\text{B})/\text{electrolyte}$  interface model indicated that the charge transfer resistance  $R_c$  and the passivating film resistance  $R_f$  of the spherical  $\text{TiO}_2(\text{B})$  were much smaller than those of the needle-like one. The spherical  $\text{TiO}_2(\text{B})$  particles with a very good electronic connection between  $\text{TiO}_2(\text{B})$  particles and the carbon conductor are considered to have a large available surface area for the charge transfer reaction. The high-rate discharge and the long-cycle life performance of the spherical  $\text{TiO}_2(\text{B})$  electrode are attributed to the good electronic connective property and small values of  $R_c$  and  $R_f$  compared to those of the needle-like one. Lithium-ion cells using the spherical  $\text{TiO}_2(\text{B})$  anodes and  $\text{LiNi}_{0.8}\text{Co}_{0.1}\text{Mn}_{0.1}\text{O}_2$  cathodes have been developed for automotive and stationary power applications. It was demonstrated that the  $\text{TiO}_2(\text{B})/\text{LiNi}_{0.8}\text{Co}_{0.1}\text{Mn}_{0.1}\text{O}_2$  cells with a capacity of 2.8 Ah and a high energy density of 100  $\text{Wh kg}^{-1}$  exhibited a high output power density of 1800  $\text{W kg}^{-1}$  for 10 s pulse and a long cycle life of more than 3000 cycles.
